SUMMARY

A non-linear mathematical model of the UH-60A BLACK HAWK helicopter has been developed under Contract NAS2-10626. This mathematical model, which is based on the Sikorsky General Helicopter (Gen Hel) Flight Dynamics Simulation, provides the Army with an engineering simulation for Performance and Handling Qualities evaluations. Initially it will be applied in an analysis mode with eventual application to real time pilot-in-the-loop simulation.

This mathematical model is a total systems definition of the BLACK HAWK helicopter represented at a uniform level of sophistication considered necessary for Handling Qualities evaluations. The model is a total force, large angle representation in six rigid body degrees of freedom. Rotor blade flapping, lagging and hub rotational degrees of freedom are also represented. In addition to the basic helicopter modules, supportive modules have been defined for the landing interface, power unit, ground effects and gust penetration. Information defining the cockpit environment relevant to pilot-in-the-loop simulation is presented. This same model was activated on Sikorsky's DEC PDP KL10 computer to generate check cases for use during the validation of the simulation at NASA.

Volume I of this report defines the mathematical model using a modular format. The documentation of each module is self-contained and includes a description, mathematical definition and input for the BLACK HAWK. Volume II provides background and descriptive information supportive to an understanding of the mathematical model.

2.0 INTRODUCTION

This report is Volume I of two volumes, which document the mathematical model of the UH-60A BLACK HAWK helicopter. This work was funded under Contract NAS2-10626 by the U.S. Army Research and Technology Laboratories (AVRADCOM) Ames Research Center.

The objective of this contract was to provide the Army and NASA with a well documented, operational and verified engineering simulation of the BLACK HAWK helicopter. This work, undertaken by Sikorsky, provides the Army with a flying qualities analysis methodology for the BLACK HAWK helicopter which could eventually be extended to a real time pilot-in-loop simulation. The mathematical model provided under this contract is a total system, free flight representation based on the Sikorsky General Helicopter (Gen Hel) Flight Dynamics simulation. It is defined at a uniform level of sophistication currently considered appropriate for handling qualities evaluations. This model is also considered to give representative performance trends, but should not be used to define critical performance characteristics. The modular format presented facilitates the introduction of additional or more sophisticated modules.

Volume I of this report documents the basic BLACK HAWK mathematical model, and in addition, defines supportive routines developed by Sikorsky under this contract. These routines include a landing interface, power unit, ground effects and rotor gust penetration models. Presented in this volume is an Overview of the Simulation Model, Section 3, followed by a Description of the BLACK HAWK helicopter in Section 4. Section 5 contains the documentation of the Simulation modules. Each of the module definitions is segregated with its own Table of Contents. Section 6 contains information defining the BLACK HAWK cockpit relevant to pilot-in-the-loop simulation. A single copy Appendix to Volume I, containing extensive program verification data generated from a similar model on the Sikorsky Simulation Facility, provides NASA and Sikorsky with the necessary information for validating the BLACK HAWK helicopter simulation on the Ames Simulation facility.

Volume II of this report documents the derivation of the equations, the assumptions inherent in the model and provides supportive discussion to aid in the understanding of the mathematical model.

3.0

OVERVIEW OF THE SIMULATION MODEL

The mathematical model of BLACK HAWK provided under this contract is based on the Sikorsky General Helicopter (Gen Hel) Flight Dynamics Simulation. This model is a generalized, modularized analytical representation of a total helicopter system. It normally operates in the time domain and allows the simulation of any steady or maneuvering flight condition which can be experienced by a pilot.

The overall structure of the model is presented on figures 3.1 and 3.2 in functional and block diagram format respectively. The solution in terms of aircraft motion is obtained iteratively by summing the component forces and moments acting at the aircraft's center of gravity and subsequently obtaining the body axes accelerations. Resulting velocities and displacements then condition the environment for the components on the next pass through the program. The datum axes system used are a set of right coordinate body axes with the origin at the fuselage center of gravity. The X axis points towards the nose of the aircraft and is parallel to the center line of the aircraft. All calculations are related to this axis system. The final aircraft motion is transferred into earth axes for simulator, VFR display and instrumentation drives. The mathematical module defining the equations of motion are presented in Section 5.10.

The basic model is a total force, non-linear, large angle representation in six rigid body degrees of freedom. In addition, rotor rigid blade flapping, lagging and hub rotational degrees of freedom are represented. The latter degree of freedom is coupled to the engine and fuel control. Motion in the lag degree of freedom is resisted by a non-linear lag damper model.

The total rotor forces and moments are developed from a combination of the aerodynamic, mass and inertia loads acting on each simulated blade. The rotor aerodynamics are developed using a blade element approach. The angle of attack and dynamic pressure on individual blade segments are determined from the three orthogonal velocity components. These arise as a result of airframe motion, rotor speed, blade motion and downwash resulting from the generation of thrust. In the latter case, which represents the air mass degree of freedom, a uniform downwash is derived from momentum considerations, passed through a first order lag, and then distributed first harmonically as a function of rotor wake skew angle and the aerodynamic hub moment. Finally, blade geometric pitch is summed with the inflow angle of attack to obtain the total angle of attack at the blade segment. The full angle of attack range for blade aerodynamics is represented as a function of Mach number.

Blade inertia, mass and weight effects are fully accounted for and their resulting loads, dependent on blade and aircraft motion, are added to the aerodynamic loads for each blade. This summation gives the shear loads on the blade root hinge pins. Total rotor forces are obtained by summing all the blade hinge pin shears with regard to azimuth. Rotor moments result from the offset of the hinge shears from the center of the shaft. Blade flapping and lagging motion is determined from aerodynamic and inertia moments about the hinge pins. During one pass through the program all segments and all simulated blades are computed. If because of execution time considerations the simulated number of blades are not made equal to the actual number, then they are redistributed in azimuth accordingly. The mathematical module defining the rotor is presented in Section 5.1.

The fuselage is defined by six component aerodynamic characteristics which are loaded from wind tunnel data which have been extend analytically to large angles. The angle of attack at the fuselage is developed from the free stream plus interference effects from the rotor. These interference effects are based on rotor loading and rotor wake skew angle. Local velocity effects are not accounted for. The mathematical module defining the fuselage is presented in Section 5.2.

The aerodynamics of the empennage are treated separately from the forward airframe. This separate formulation allows good definition of non-linear tail characteristics that would otherwise be lost in the simplifications of multivariate total aircraft maps. With this approach, changes to the empennage can be made without reloading basic airframe maps. The angles of attack at the empennage are developed from the free stream velocity, plus rotor wash and airframe wash. Dynamic pressure effects from the airframe are accounted for by factoring the free stream velocity component. By necessity the wash and dynamic pressure effects are averaged over the stabilizing surfaces. The tail rotor is represented by the linearised closed form Bailey theory solution. Terms in tip speed ratio greater than μ squared have been eliminated. The airflow encountered by the tail rotor is developed in the same manner as the empennage. An empirical blockage factor, due to the proximity of the vertical tail, is applied to the thrust output. The mathematical modules defining the Empennage and tail rotor are presented in Sections 5.3 and 5.4 respectively.

The flight control system for BLACK HAWK presented in this model covers the primary mechanical flight control system and the Automatic Flight Control System (AFCS). The latter incorporates the Stability Augmentation System (SAS), the Pitch Bias Actuator (PBA), the Flight Path Stabilization (FPS) and the Stabilator mechanization. These automatic control functions collectively enhance the stability and control characteristics of the BLACK HAWK. The analytical definition of the control system given in Section 5.5 incorporates the Sensors, shaping networks, logic switching, authority limits and actuators. Some of these components have wide band-widths which are beyond the frequencies normally associated with piloted simulation. They have been included for completeness and accuracy in analytical evaluations. The model provided represents the control system in a complete manner except for the FPS. In this case only the attitude hold and turn features have been defined.

The engine/fuel control model provided with this simulation is a linearized representation with coefficients which vary as a function of engine operating condition. The model adequately provides for closing the rotor shaft speed loop throughout the normal operating envelope of the helicopter. However, maneuvers which result in significant rotor speed excursions may result in discrepancies in the simulation. This engine module should not be used for engine performance evaluation. The modular formulation does however, facilitates the introduction of a sophisticated model if necessary at a later time. The interface of the engine with the rotor module, shown on Figure 3.3, is via the rotor clutch. This is programmed to disengage the rotor shaft from the engine if rotor required torque drops below zero. Under these circumstances, the engine speed feedback to the fuel control will cause the engine to seek an operating condition dictated by the control. The clutch will reengage when the rotor speed drops below power turbine speed. The engine fuel control equations are presented in Section 5.6.

The landing interface module, Section 5.7, allows for ground contact. It is a generalized representation consisting of a landing gear force reaction model complete with all necessary space/body geometry calculations to track a free helicopter during a landing onto level ground. The landing gear is represented by separate non-linear tire and strut dynamic characteristics. Tire in-ground-plane loads are developed as a non-linear function of the tire deflection and normal load. These forces are adjusted depending on the friction criteria which determines tire skid properties at the ground plane. The strut is simulated by an isentropic air spring and velocity squared damper in parallel. The output loads from the three landing gears are finally transferred to the center of gravity where they are summed with other external forces and moments.

Section 5.8 defines a simplified ground effects model. During the development of this module it was evident that anything more than a simple model based empirically on distance above the ground plane, was beyond the scope of this contract. The model provided, adjusts the downwash at the rotor (and therefore rotor loads) as a function of height above the ground plane and forward speed (in terms of rotor wake skew angle).

The gust penetration routine documented in Section 5.9 provides for a gust front passing across the rotor disc from any direction. Behind the front, gust velocities are varied with distance from the front. The variation can be prescribed by a choice of several discrete velocity profiles or a continuous turbulence form due to Dryden. Each rotor blade element and the aerodynamic centers of fuselage and tail components may be subjected to horizontal and vertical gust velocities whose magnitude is a function of the geometric distance from the traversing gust front. Thus penetration or velocity distributional effects are almost fully accounted for in the rotor simulation and are adequately dealt with in the fuselage/tail model.

4.0 Description of the BLACK HAWK Helicopter

The UH-60A BLACK HAWK, shown in the figures 4.1 and 4.2, is a utility transport helicopter developed by Sikorsky for the Army under the UTTAS program. This medium-sized helicopter is designed to carry eleven combat-equipped troops and a crew of three. The Basic Structural Design Gross Weight is 16,825 lbs. with a maximum Alternate Gross Weight of 20,250 pounds. Missions include: Troop Assault, Aeromedical Evacuation, Aerial Recovery and Extended Range Missions. The BLACK HAWK has a maximum level flight speed in excess of 160 knots and a diving speed in excess of 170 knots.

The BLACK HAWK has a single main rotor and a canted tail rotor as shown on the general arrangement drawing, figure 4.3. A list of physical characteristics is given on Table 4.1. The main rotor consists of four fully articulated titanium/fiberglass blades which are retained by a flexible elastomeric bearing in a forged titanium single piece hub and restrained in plane by a conventional hydraulic lag damper. The 11.0 feet diameter four bladed tail rotor is a bearing-less cross-beam arrangement with the shaft tilted 20 degrees upwards. Both rotors have an SC 1095 aerofoil section. The aircraft is powered by two General Electric Company, T 700-GE-700 engines mounted on top of the cabin which together provide approximately 2,800 h.p. at normal continuous rating. These engines have Hamilton Standard hydraulic, and General Electric Company electronic fuel control components. The drive system consists of main, intermediate, and tail gear boxes with interconnecting shafts.

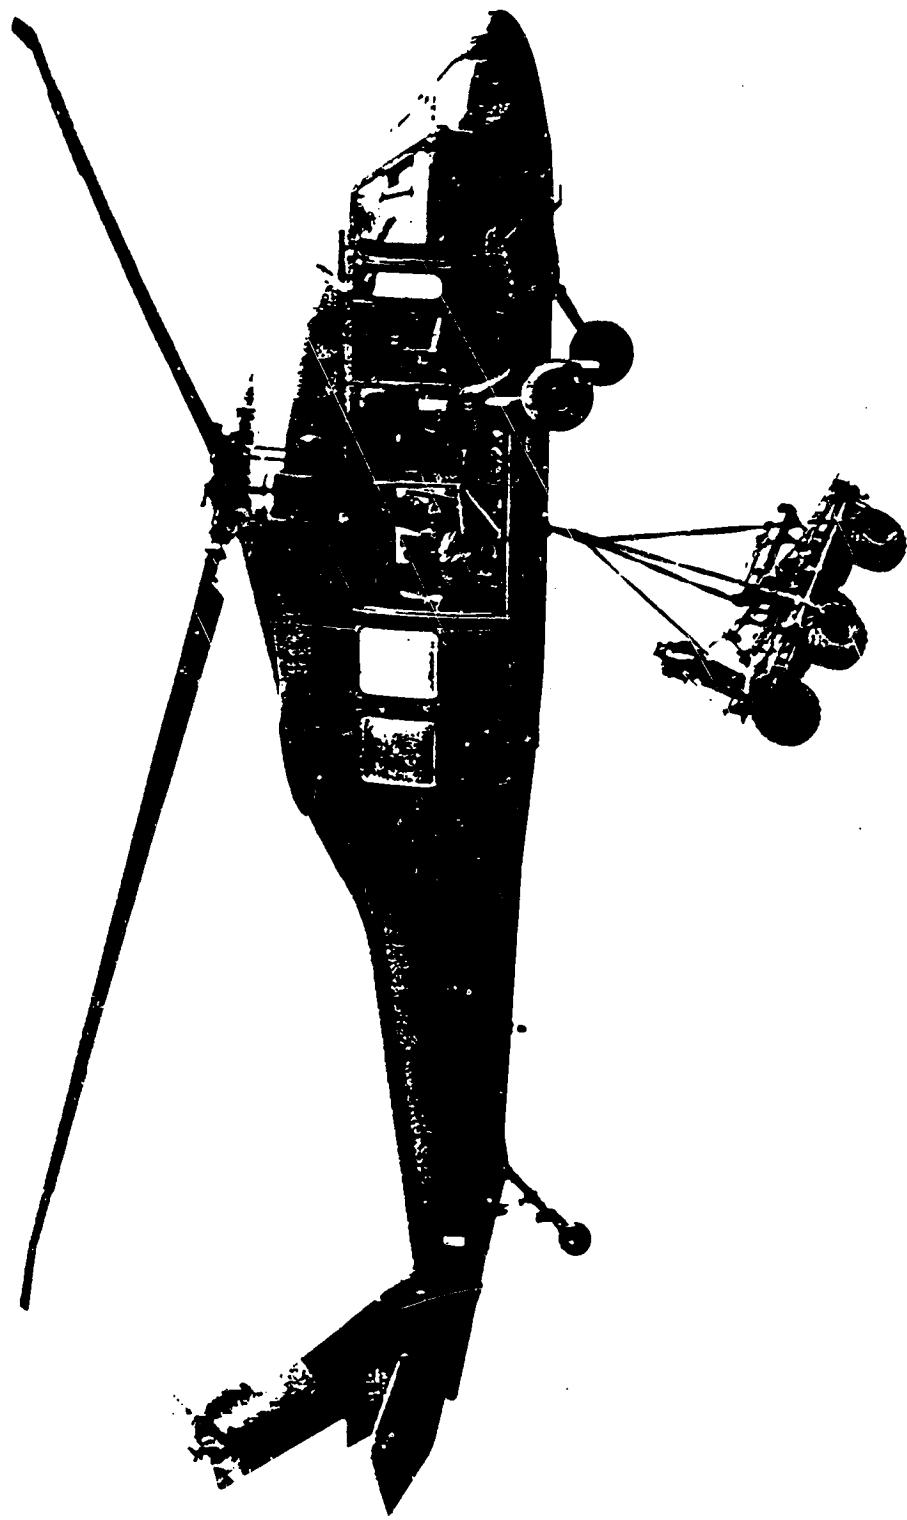

The flight control system on the BLACK HAWK is a redundant hydro-electrical-mechanical system. It includes three two stage main rotor servos, a Stability Augmentation System (SAS), a Flight Path Stability System (FPS), and a triple redundant hydraulic supply. The horizontal tail rotates from a positive angle of about 40° in hover up to zero with increasing forward speed.

A summary of the mass properties characteristics is given on Table 4.2. Recommended overall longitudinal center of gravity limits are given on figure 4.4.

A more comprehensive description of the BLACK HAWK helicopter is given in References 4.1.1, 4.1.2, and 4.1.3.

5.1 Main Rotor Module

5.1.1 Module Description

The main rotor model is based on a blade element analysis in which total rotor forces and moments are developed from a combination of aerodynamic, mass and inertia loads acting on each simulated blade. The blade segment set up option defined for this Black Hawk model is that of equal annuli area swept by the segment. This technique allows the number of segments to be minimized and distributes the segments towards the higher dynamic pressure areas.

The total forces acting on the blade are derived from the total acceleration and velocity components at the blade together with control inputs. Accelerations develop from body motion and blade motion. Velocity components are made up of body velocities, gust velocities, the rotor's own downwash and blade motion.

Before calculations at the blade segment can be executed several axes transformations must be implemented. Initially body axes angular and translational accelerations and velocities are transferred to the rotor hub and rotated through the shaft inclination angles i_1 and i_2 into rotor shaft axes. These angles with positive rotation of i_1 about the Y_H axis followed by i_2 about the resulting X_H axis are shown in Figure 1.1.1. The Body velocities are non-dimensionalized by rotor tip speed ($S_T R_T$) to conform with usual helicopter analysis practice. Motion accruing from the rotor shaft degree of freedom is derived from the engine module.

The rotor airmass degree of freedom is primarily based on a uniform downwash distribution developed from rotor thrust by application of momentum theory. This uniform downwash, which is passed through a first order lag, is modified to account for the changing distribution with forward speed and aerodynamic pitching and rolling moment loading on the rotor. In the first case the resulting uniform downwash is distributed 1st harmonically around the azimuth as a cosine function depending on the inclination of the rotor wake. The desirability of including this first harmonic distribution, which results in a uniform downwash at hover and a weighted distribution towards the aft of the rotor disc at high speed, is discussed in Reference 1.6.1. Since this effect is really dependent on the resultant velocity vector a lateral velocity term is also added. The desirability of adding a harmonic distribution of downwash depending on aerodynamic rotor moments has not been established for Black Hawk but the necessary equations are incorporated for completeness.

The remaining contribution to the velocities at the blade segment is that due to blade motion. Blade flapping and lagging velocities and angles are obtained by application of a Fourier prediction technique, rather than direct integration of acceleration. This approach is derived in Reference 1.6.2. This method although simple has been shown to be stable and accurate for the frequencies of concern in helicopter stability and control evaluations.

The blade segment total velocity components are developed in three parts. Those independent of segment position, those dependent on segment position and interference effects made up of downwash and gust effects. The velocities at the blade segments are obtained by transforming the fixed shaft vectors into the rotating hub axes system, then transferring to the blade hinge position, transforming into blade span axes through the Euler angles ϕ (flapping) and δ (lagging) and finally transferring to the segment position on the blade. These transformations are illustrated on figure 1.1.2. These total velocity components are subsequently used to calculate the resultant velocity, local Mach number, yawed angle of attack and flow yaw angle. It should be noted that the radial component of velocity is omitted in calculating the Mach Number which is used in the aerodynamic map look-up. Reference 1.6.3, which describes the use of simple sweep theory, indicates that Mach Number should be based on the unyawed component of flow.

The total local segment angle of attack on the blade is made up of the blade local pitch angle and the yawed angle of attack at the segment. The former is made up of the control impressed pitch (collective θ_{CUFF} , cyclic A_{1S}, B_{1S}), pitch/flap coupling (S_2), pitch/lag coupling (α_1), preformed blade twist and a dynamic component of blade twist due to torsional elastic deformation. This empirical dynamic component is prescribed harmonically based on blade loading. The yawed angle of attack is complicated by the requirement to resolve blade pitch into the local stream direction as shown in Figure 1.1.3. The resulting equation assumes the series approximation for the tangent of blade pitch.

The treatment of the blade segment aerodynamic force calculation is completely non-linear. Lift and drag characteristics are provided for the range $-180 \leq \alpha \leq 180$. Bivariate maps as a function of angle of attack and Mach Number are used in the range $-30 \leq \alpha \leq +30$ allowing good definition of blade stall. The complete coverage of angle of attack allows good definition of aerodynamic characteristics on the retreating blade side of the disc. This is important at high advance ratios. The blade segment lift coefficient is determined by applying simple sweep theory to the unyawed blade aerodynamic data. This is rigorously applied in the linear lift range where the entry to the unyawed lift coefficient is transformed by the cosine of the yaw angle (i.e. $\alpha_{TRANS} = \alpha_y \cos \gamma$) and the entry Mach Number is a function of the unyawed component of flow. At higher angles of attack some liberties are taken where sweep theory is not valid. These steps are taken to avoid discontinuities in blade lift data as the blade proceeds around the azimuth. Discontinuities can result in an unstable flapping and lagging solution. The application of sweep theory to the determination of drag is not well established. For this model, drag is determined by entering the drag map data with the actual yawed angle of attack. ($\alpha_{TRANS} = \alpha_y$). A development of sweep theory can be found in Reference 1.6.3. Sikorsky evaluations of this theory, as applied to rotors, are documented in Reference 1.6.4. i.e map entry logic is developed in the equations. It should be noted that a tip loss factor is applied to the tip segment. Univariate and bivariate maps of blade lift and drag coefficients as a function of α_{TRANS} and Mach Number are given in Section 5.1.5. The aerodynamic segmental loads are resolved from local wind axes into blade span axes and summed along each blade to obtain root shears at the hinge. These forces are subsequently transformed into rotating shaft axes. It should be noted that β and δ are Euler angles and order of treatment must be observed. The aerodynamic moments used in the flapping and lagging motion equations are calculated at this point in the flow. Also, it is convenient to develop the aerodynamic feedbacks for the rotor downwash calculation at this time.

The blade inplane or lagging motion is restrained by a damper system. In the case of Black Hawk the damper is non-linear and the kinematics of this system are complicated by geometry. A generalized representation is utilized as presented on Figure 1.1.4. Essentially the relative positions of the pick-ups of the damper on the hub and blade are tracked. From these values an axial velocity is determined. This velocity is used to enter the map data presented in Section 5.1.5. The output of this map, which is an axial force, is multiplied by the instantaneous moment arm to obtain the damper moment about the hinge. Although flapping restraint equations are included they will not be activated for Black Hawk.

The contributions to the lagging and flapping motion about the hinge are the aerodynamic moments, the hinge restraint moments and the inertia moments. The aerodynamic and hinge restraint components have been previously discussed. The inertia components have been explicitly introduced into the flapping and lagging equations of motion. It should be noted that lagging motion takes place in an intermediate set of blade span axes because of the definition of the Euler angles. Also small terms have been eliminated from these equations. A software provision to inhibit the lagging degree of freedom has been incorporated.

Before the final shear forces and hub moments can be developed it is necessary to calculate the inertia shear loading on the hinge pins. Again small terms have been eliminated. Subsequent to these calculations the three component total shears at the hinge are determined and the total rotor forces in fixed shaft axes at the hub center developed. The rotor hub moments result from a combination of the shear forces at the hinge pins and moments from the blade hinge restraint. An arithmetic manipulation of the equations is introduced on these final equations which allow the simulated blades to be different from the actual number. This artifice is intended for use in piloted simulation where computer execution time is critical. With the lagging degree of freedom operating, the major portion of rotor torque is developed through the lag damper. Therefore, if lagging degree of freedom is selected out, an alternative equation containing the aerodynamic moment must be introduced as specified.

The oscillating nature of the rotor forces and moments make it expedient to filter the outputs under some circumstances. A simple first order filter is used. The final rotor forces and moments are obtained by transforming the filtered shaft axes forces and moments into body axes with the origin at the center of gravity. These are eventually summed with other component outputs to give the total external forces and moments at the center of gravity.

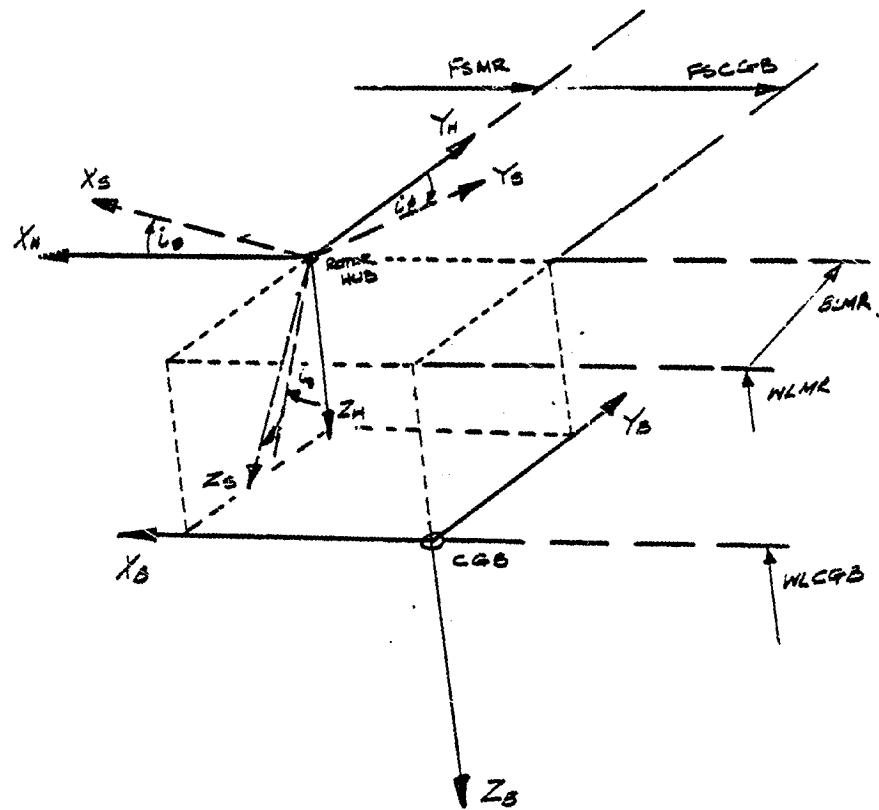

It is necessary to make provision in these final rotor outputs for the option of selecting to run with the engine module in or out. If the engine is selected out, perfect rotor speed governing is assumed and the shaft torque reaction on the airframe is assumed equal to rotor required torque. If the engine module is activated then its output torque is introduced into the airframe.

Finally, the rotor wake skew angle is determined. This is the angle that the center line of the rotor wake makes with the rotor shaft. It is the dependent parameter used to establish the variation of rotor wash on the fuselage, wing and tail.

The sequencing of the program flow in the main rotor is critical and should follow the equation flow in Section 5.1.2.

A block diagram of the Main Rotor Module is given on figure 1.1.5. All input data for the Black Hawk Main Rotor is specified in Section 5.1.5.

5.2 Fuselage Module

5.2.1 Module Description

The effects of rotor wash on the airframe have been treated in gross terms. No attempt has been made to determine the local flow under the rotor disc and apply it to an element analysis of the fuselage. The implication of the method used is that any variations in local velocity effects have been ignored. It is considered that the technique used provides the essential effects of more interference velocity with increased rotor load, and varies as the rotor wake deflects rearward with increased forward speed.

The angles of attack and sideslip are derived from the body axes components of velocity. These comprise the components of flight path velocity, gust components and rotor downwash. The definition of the angles are those used in the wind tunnel. That is, angle of attack is the geometric angle subtended by the model relative to tunnel axis at zero yaw angle. It does not change with yaw angle. Angle of sideslip, equal to minus yaw, is defined as yaw table angle in the horizontal plane of the tunnel, irrespective of angle of attack. It should be noted that these angles are not Euler angles.

The fuselage aerodynamic characteristics are specific to the Black Hawk helicopter. They are not generalized in any way and are derived directly from wind tunnel tests. The aerodynamic coefficients in terms of ft^2 and ft^3 , for forces and moments respectively, are presented as functions of angle of attack and sideslip in Section 5.2.5. These wind axes forces and moments are subsequently transformed into body axes at the fuselage center of gravity. The data obtained from wind tunnel tests up to post stall conditions must be extended to $+90^\circ$ to cover the low speed flight regimes. Near hover, the most important forces (tail off) are the vertical drag and side force. These can be estimated fairly accurately. Because of the definitions of angle of attack and sideslip the transformation equation gives invalid body axes forces and moments when these angles approach 90° .

ORIGINAL PRINTING
OF POOR QUALITY

DOCUMENT NO. SER 70452

To avoid problems during pilot-in-the-loop simulation, filters are presented which fade out the transformation and introduce fixed body axes parameters, estimated specifically for hover and low speed flight. For open loop analysis the longitudinal degrees-of-freedom are representative. It should be noted however, that inaccuracies will be encountered in pure side flight (i.e., rotor side wash on the fuselage does not exist). A block diagram indicating the fuselage module flow is presented on figure 2.1.1.

5.3 Empennage Module

5.3.1 Module Description

This module calculates the aerodynamic forces on the horizontal and vertical tail surfaces resulting from the local airflow. The velocities are derived at, and the aerodynamic forces assumed to act at, the panel center of pressure. Aerodynamic forces are developed in the local flow wind axes system and subsequently transferred to the body axes system at the fuselage CG as defined on Figure 3.1.1. The overall module equation flow is shown in block diagram form on Figure 3.1.2.

The tail can experience aerodynamic interference effects from many sources. Components of flow from the main rotor and fuselage are define at present in this module. However, the equations are formulated to allow easy insertion of other components. Three components of rotor wash are developed as a function of rotor wake skew angle and blade longitudinal flapping. Tail dynamic pressure blockage and downwash from the forebody are developed as a function of angle of attack and sideslip. Small downwash/sidewash angles are assumed and the velocity delayed to account for the time taken by the airflow to reach the tail.

The total velocity components for the tail are made up of contributions from the basic body axes translational and angular velocities, gust effects, rotor wash, fuselage downwash and sidewash. Dynamic pressure loss is introduced by factoring the components of the free stream flow. The actual total dynamic pressure at the tail is calculated from the resultant velocity vector. This allows a more representative definition of dynamic pressure at low speeds where downwash from the rotor predominates the flow at the tail. The lift and drag forces at the tail are obtained from isolated tail data and are a function of tail total angle of attack. In the case of the vertical tail, angle of attack has the same connotation as sideslip. The lift and drag forces in local wind axes are resolved into body axes at the tail. (Moments from the tail about its own axis are not accounted for.) Finally, the component forces at the empennage are transferred to the CG together with the corresponding moments.

5.4 Tail Rotor Module

5.4.1 Module Description

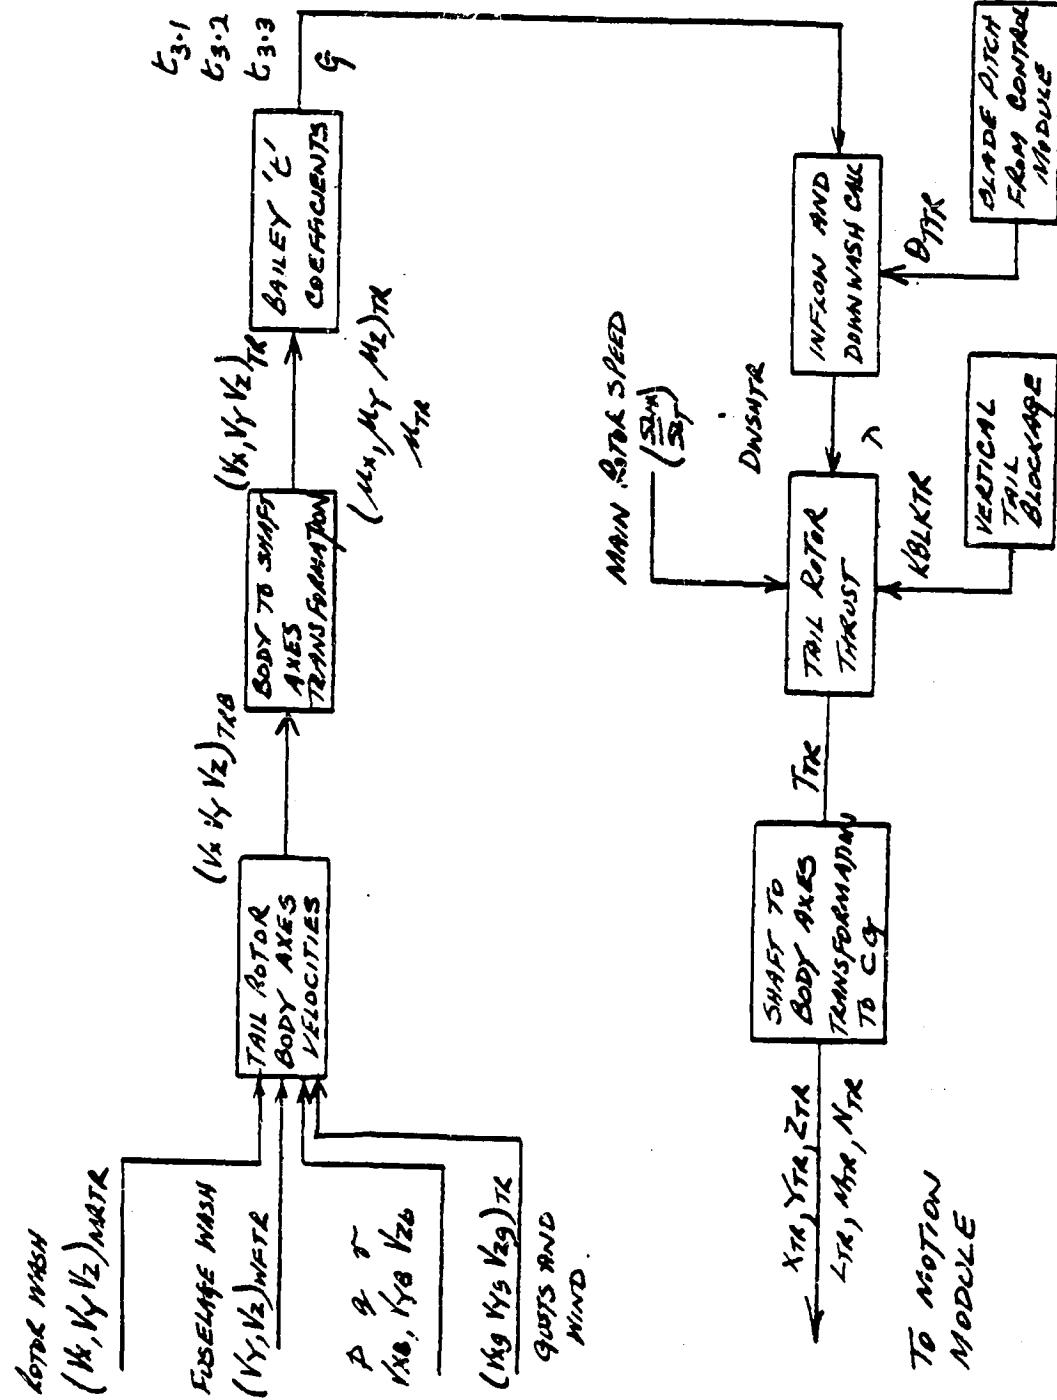

This module calculates the forces and moments at the center of gravity which are generated by a canted tail rotor. This rotor is represented basically by a simplified, closed form, Bailey Solution as developed in Reference 4.6.1. All terms in tip speed ratio (μ) greater than squared have been eliminated. In order to obtain the actual tail rotor collective pitch value, (θ_{TR}), the Bailey equations have been modified to account for δ_3 (pitch-flap coupling). This reduces the blade pitch which is impressed by the control system.

The airflow impinging on the tail rotor is developed from the free stream, rotor wash and fuselage sidewash, together with body angular rate effects. The total components of velocity are resolved through the cant angle into the tail rotor shaft axes system.

The Bailey theory equation is normally presented as the thrust coefficient in terms of the 't' coefficients. It should be noted that the equations have been manipulated to obtain an expression for downwash. This was found to be necessary to obtain an unconditionally stable solution. It is important that program flow follows the equation flow for a stable tail rotor solution (Figure 4.1.1).

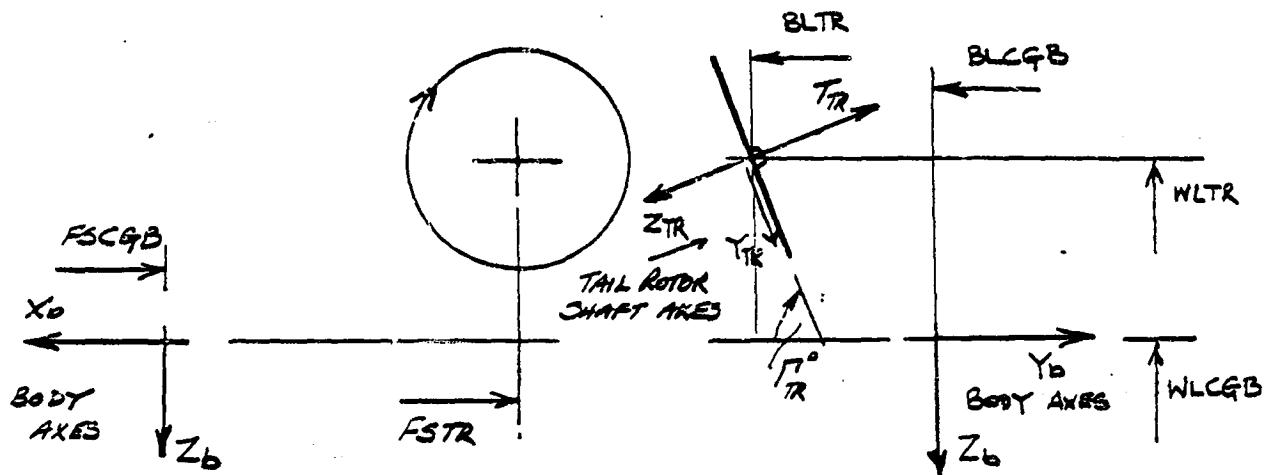

A blockage factor K_{TBALK} is applied to the final thrust output to account for the proximity of the vertical tail. This correction is empirical and based on flight test data of other helicopters.

This simplified tail rotor model only calculates thrust. No account of H force is included in the final tail rotor force outputs. The tail rotor thrust is finally resolved into force and moments in body axes, at the center of gravity.

5.4.2 TAIL ROTOR MODULE EQUATIONS

GEOmetry

$$F_{TR} = \frac{(F_{STR} - F_{SCGB})}{12}$$

5.5 FLIGHT CONTROL SYSTEM MODULE

5.5.1 Flight Control Simulation Module Description

The simulation of the flight control system is presented entirely in terms of block diagrams indicating the transfer function between signals. The Background information presented in Section 3.5 of Volume II complements this description of the control system simulation. An overview of the control system simulation nomenclature, for the various elements, is presented on Figure 5.1.1. The block diagrams, subsequently presented, are aligned with the flow of this figure. It will be noted in studying this section, that the bandwidth of some control system components is wide. This leads to time constants of some of the transfer functions being small. For completeness these components have been retained in the model, thus making it necessary to provide a test for cycle time in the corresponding algorithms to ensure unity gain if cycle time is large relative to the function's time constant.

- (a) Sensors - The transfer functions for the sensors are presented in Figure 5.1.2.
- (b) Stability Augmentation System (SAS) - The simulation definitions for pitch, roll and yaw SAS channels are shown on Figures 5.1.3 (a), (b), and (c) respectively. Each figure incorporates the representation of the digital and analog SAS channels. In general, the helicopter motion sensed by the gyroscopes is passed through signal conditioning filters before being shaped by the SAS networks. The signal is then processed through a washout, if required, and the 2:1 gain change switch. The switch definition is - ON/ON, both channels working at gain 1.0, ON/OFF, digital channel only working at gain 2.0, OFF/ON, analog channel only working at gain 2.0. Finally, the signal is restricted in amplitude by a 5% authority limit. In the case of the digital channel, the signal is passed through a zero order hold to account for update delays. A switch in the yaw channel inhibits the lagged rate term at speeds above 60 knots and introduces lagged lateral acceleration for aid in turn coordination.

The following logic applies for all control system channels:

- In the IC Mode: 1. Outputs of all synchronizers are zero.
2. Outputs of all integrators are zero or have defined initial values.

In the Compute Mode: The logic is defined on the block diagrams.

- (c) Pitch Bias Actuator (PBA) - The PBA representation is presented on Figure 5.1.4. The input signals are derived as indicated. It should be noted that the pitch rate signal is picked off

downstream of the signal conditioning. The three input signals are limited, passed through a gain and summed to obtain the signal output to the PBA actuator. The actuator travel is restricted by a $\pm 3\%$ /sec rate limit and a $\pm 15\%$ authority limit. Because the PBA algorithm is computed by the digital computer, the simulation includes a zero order hold.

- (d) Flight Path Stabilization (FPS) - The simulation representation of the pitch, roll, and yaw Flight Path Stabilization channels are presented on Figures 5.1.5 (a), (b) and (c) respectively. The synchronization elements in the model must track during the simulation trimming phase and in the IC mode. During the compute mode, they must track with the FPS off. The FPS shaping networks are relatively straightforward, however, a degree of complication is introduced by the automatic turn coordination capability. On the helicopter the turn switch is enabled by several channels of complex logic. For this simulation it is recommended that the switch be enabled by one path only.

FPS ON, $VXBKT > 60$ kts, plus trim release
 pressed, plus $\theta_b > 20$

Exit is by feet on the pedals and trim release pressed. For analysis purposes the turn switch can be enabled as required. Since the FPS is computed in the digital computer, the final output to the trim actuator is passed through a zero order hold. The trim actuator has 100% authority within certain control force constraints and is rate limited at 10%/sec.

- (e) Mechanical Control System - In addition to its function as a mixing unit for control coupling, this area in the simulation is used to bring together the various elements of the control system computed upstream. The representations of the four primary controls, main rotor collective blade pitch, lateral cyclic blade pitch, longitudinal cyclic blade pitch and tail rotor collective pitch are shown on Figures 5.1.6 (a), (b), (c) and (d) respectively. The longitudinal cyclic pitch channel will be used for purposes of discussion. The outputs from the digital and analog SAS channels are summed and processed through the SAS actuator dynamics, resulting in actuator travel in inches (XBILS). This is summed with the PBA (XBBAS), the FPS (XBOLS) and the pilot control stick input (XB+2). The trimming algorithm input (XB+1) is added in the simulation at this point for cases where trim is accomplished using the control sticks. The resultant linkage motion is converted into equivalent degrees of longitudinal cyclic before being summed with coupled motion from other controls in the mixing unit. The output from the mixing unit B1SMIX is modified by the primary servo dynamics giving the final longitudinal cyclic impressed on the main rotor. Additional inputs are added at this point for use in analysis. Travel limits for the rotor head are given on page 5.5.20.

(f) Stabilator - The representation of the analog network controlling the stabilator is presented on figure 5.1.7. The network provides for the feedback of velocity, collective stick, lateral acceleration and pitch rate scheduled as a function of forward speed. The output from the network is passed through the dynamics of the limited rate tail servo. For the simulation provision is made for an alternative input (STBSET) for use in analysis.

5.6 ENGINE/FUEL CONTROL MODULE5.6.1 Module Description

This engine/fuel control model is basically a linearized representation with coefficients which vary as a function of engine operating condition. This model adequately provides for closing the rotor shaft speed loop throughout the normal operating envelope of the helicopter. However, maneuvers which result in significant rotor speed excursions may result in discrepancies in the simulation. All the usual restrictions and assumptions of linear simulation are applicable and should be observed. In an analysis mode deviations from trim are not large, but for pilot-in-the-loop operation some means of continuously synchronizing the steady state engine torque must be developed. This engine module should not be used for engine performance evaluation.

The elements of the model are shown on the simplified block diagram of Figure 6.1.1. They comprise the control interface with Gen. Hel., fuel control, gas turbine, power turbine, and rotor shaft speed degree-of-freedom interface with the Gen. Hel. rotor. This model which derives total S.H.P. at the rotor shaft by appropriately factoring the output from one engine is applicable for evaluations in the governed range. A transmission clutch is represented allowing disconnect of the rotor drive at zero torque required by the rotor. This allows autorotations and recoveries to be executed.

Initialization of the engine/fuel control module is accomplished by using the steady state engine performance required to trim the helicopter simulation in free flight.

A basic background to the complete T.700 engine/fuel control system is given in references 6.6.1 and 6.6.2. A detailed block diagram of the simulation is given in Figure 6.1.2.

The basic engine control system operation is through the interaction of the Electrical (ECU, Figure 6.1.3), and Hydromechanical (HMU) control units. In general, the HMU provides for gas generator speed control and rapid response to power demand. The ECU trims the HMU to satisfy the requirements of the load so as to maintain rotor speed. The Load Demand Spindle (LDS) is a function of collective pitch setting and provides compensation to reduce rotor transient droop. Any steady state errors resulting from inconsistent collective positioning are trimmed by the ECU. In the simulation, this is trimmed by the difference between actual gas generator speed (from steady performance data and that resulting from the collective setting). These characteristics are implemented in the simulation.

In general, isochronous governing of the rotor speed is maintained by developing an error relative to the reference speed and commanding more or less power to stabilize at the required speed. Basically, this process involves the speed error demanding a change in gas generator speed (N_{GG}) via the shaping of the ECU electrical network, Figure 6.1.3. This signal is summed with the LDS input in the HMU, and compared with the actual gas generator speed. The subsequent error, commands changes in fuel flow leading to a higher or lower gas turbine speed and changes in the gas flow. This in turn provides increased or decreased power at the driveshaft from the power turbine. In the simulation, torque output from one engine (Q_{pt}) is derived from three sources. From direct changes in fuel flow, from changes in gas generator speed and as a result of changes in power turbine speed. These increments are summed to obtain a total change in engine torque from trim and subsequently factored by the number of operating engines and engine/rotor gearing ratio, to obtain engine torque output to the rotor shaft.

The interface with the main program is presented on Figures 6.1.1 and 6.1.2. The rotor can be visualized in simple terms as a damper responding to changes in rotor speed. However, the significant effect of the rotor relates to the changes in torque loading as a result of control inputs and changing states. Rotor shaft accelerations result from torque differences in output from the power turbine and torque required by the rotor. The simulation is initialized at trim such that the rotor is at the input speed and $\Delta Q=0$. A clutch is modelled, Figure 6.1.4, which will disengage the rotor from the engine at a zero rotor torque level. When Gen Hel is being executed in combination with the engine, total engine torque must replace rotor torque as a reaction in the airframe equations.

5.7 LANDING INTERFACE MODULE5.7.1 Module Description

This generalized representation consists of a landing gear force reaction model complete with all necessary space/body geometry calculations to track a free helicopter landing onto a level ground plane. The landing gear is represented by separate non-linear tire and strut dynamic characteristics as shown in Figure 7.1.1. Tire in-ground-plane loads are developed as a non-linear function of the tire deflection and normal load. These forces are adjusted depending on the friction criteria which determines tire skid characteristics at the deck surface. Finally, strut loads are summed with other external forces and moments at the helicopter CG.

Axes Systems. Two axes systems are used in this landing interface module as shown in Figure 7.1.2. All landing gear forces and moments are formulated in axes parallel to the primary body axes system passing through the CG. The space axes system of which the ground plane is set at WLFD is used to determine the landing gear proximity to the ground. Inplane friction forces are checked in the space axes system.

Landing gear geometry. In the equations defining the geometry of the landing gear, Figure 7.1.3: It is assumed that the strut moves along the line parallel to the helicopter Z axis. No account is taken of drag linkage constraints which cause the axle to move in an arc in the X-Z plane. This geometry together with the Gen Hel calculated position of the helicopter C.G. position in space, is used to establish the location of the tire, axle reference and gear reference points for each gear in space axes. These coordinates are used later to determine the proximity of tire contact and subsequent tire and strut deflections.

Determination of tire contact. The determination of tire contact, for an arbitrary orientation of the helicopter relies on establishing the length of a normal line from the ground plane to the axle reference position. When the distance along the gear line becomes less than the tire radius, contact has occurred. Subsequently, this difference is defined as radial tire deflection. In practice tire contact can occur at any point on the width of the tire. In the model the contact point is assumed to be at the center of the tire tread, irrespective of the distortion resulting from radial or axial loading.

Determination of tire inplane deflections and loads. In order to establish the degree of inplane deflection and corresponding loading on the tire, it is necessary to track the intersection of the landing gear line relative to the ground plane. Essentially two equations of the gear line, (each projected into a two dimensional plane) are solved for the intersection coordinates with the ground plane. When contact for an individual tire is established, the point of intersection is retained and on subsequent iterations through the program, tire deflection is determined by comparing the new and old gear line intersections. The coordinates of the initial contact are retained until the tire leaves the ground or is modified by the tire slipping. The latter aspect is discussed later. Following the transformation of the deflections into helicopter body axes, the three components of deflection at each tire are used to enter the "tire characteristics data file," to obtain the three components of tire force.

Determination of tire contact conditions. Following the determination of tire forces from the helicopter/ground plane relative motion, a test of the ability of the inplane friction forces to resist the applied forces, without slipping, must be established. The tire forces obtained in helicopter axes must be transferred to the ground plane for the friction check. Classical friction considerations provide for a coefficient of static friction and a coefficient for sliding friction. In the former case (when brakes are set), the maximum amount of inplane load which can be resisted without slipping, is proportional to the coefficient of friction and the normal loading. When this level is exceeded, motion will result. Then the force resisting the motion will depend on a reduced (sliding) coefficient of friction and the normal force. In practice, there is a smooth transition between the two conditions. However, the model assumes a discrete change. A further assumption is that the test for frictional loads in the model assumes that X and Y inplane components can be tested separately. In practice, the resultant force determines slip conditions. This latter assumption was made to simplify the model and facilitate the introduction of brakes. When the brakes are activated, it is assumed that the wheels are locked. For brakes off, a very low coefficient of friction is introduced into the tire X direction. The wheel degree of freedom is not currently represented and therefore spin up (say on landing) inertia loads are not calculated. If slip is not occurring, calculated tire forces are passed unchanged. If slippage is occurring, the inplane forces are set to the value for sliding friction.

Reinitialization of the original tire contact point as a result of slippage. Under conditions of no-slip the tire inplane deflection is developed from consecutive calculations of the gear line intersection with the ground plane. During slip conditions, the contact point for the tire moves and the initialization of the gear-line intersection must be revised to reflect the tire movement and establish a new value for the contact point to be used on the next pass through the program.

Acceleration of the landing gear strut. Under steady conditions, the loads transferred to the airframe by the strut will be equal to the tire reactions. However, under transient conditions, the acceleration of the unsprung mass can modify the loading. Under light loading condition (where a significant portion of helicopter weight is reacted by the rotor), the strut operates in a preload range. Under these conditions, where tire reaction load is less than the strut preload setting, tire loads are transferred to the airframe with zero strut deflection. Once the preload setting is exceeded, the strut (unsprung mass) is accelerated depending on its own dynamic characteristics, the tire applied loads and the unsprung mass. Note that logic precludes the equation flow reverting back to the preload mode until the natural transient provides a zero strut deflection condition. The strut is assumed to have velocity squared damping and an isothermal air spring. A software switch is provided which allows bypassing the strut calculation. Finally, the strut loads are transferred to the helicopter CG for summation with other external forces.

5.8.1 Module Description

This module simulates the effect of ground proximity on a helicopter by modifying the main rotor downwash equation.

The modification factor was derived from Black Hawk hover-power flight test results (Reference 5.8.6-1).

The modification factor is reduced as flight speed is increased at constant height by a wake angle correction.

It is likely that recent and on-going research on this subject (Reference 5.8.6-2) will lead eventually to an empirical model describing the local rotor inflow velocity due to the hyperbolically shaped ground vortex and its image that has been shown to exist at low speeds. Unfortunately, sufficient data for correlation of such a model has not yet been published.

5.8.2 GROUNd EFFECT MODULE EQUATIONS

$$DWSHMR = \frac{K_{CT} C_{TA}}{2 \mu_{TOT}} \left\{ \frac{1}{1 + \frac{T_{DNO} \cdot S}{\mu_{TOT}}} \right\} \cdot K_{GE}$$

$$K_{GE} = \left[1 + 0.115 \left(\frac{R}{Z} \right)^2 \left(\frac{Z}{\mu_{TOT}} \right) \right]^{-2/3}$$

$$Z = \frac{(WLMR - WLGND)}{12} - \int V_Z dt.$$

The part in square brackets [] is the ground proximity effect (usually switched to 1 when $Z > 5 \times R$), the rest of the equation is as quoted in the main rotor downwash section.

5.9 Gust Module

5.9.1 Description

This module produces local air velocities at all rotor-blade segment positions and at the fuselage and empennage aerodynamic centers, caused by various types of gusts. The input gusts may be discrete or continuous.

The output velocities are calculated in the local axis-system in which they are to be used. Thus the fuselage and tail terms are in body axes while those at the blade segments are in blade flapped and lagged axes.

The discrete gusts are characterized by having a front line designating the beginning of a disturbance, travelling through the atmosphere at velocity V_{HW} on a compass bearing ψ_w (Figure 5.9.1.1). Behind this front line, the change in air velocity can assume a step or rounded ramp or pulse shape, characterized by a magnitude V_{HGAMP} and rise-time G_{HDIS} (Figure 5.9.1.2). Since the aircraft is defined to be flying initially at V_{KTS} on compass bearing ψ_{B0} , the gust front can sweep across the aircraft (or be penetrated by the aircraft) from any direction and at any speed, by manipulating the relative speeds and compass bearings.

The continuous gusts are represented by the Dryden Model. The gust is assumed to be aligned with the aircraft heading such that only longitudinal and vertical vectors are defined. This is a necessary restriction, which avoids frequency shifts that would invalidate the gust spectrum model. At aircraft trim speeds greater than 50 ft/sec, a stationary gust field is traversed by the aircraft; at trim speeds less than 50 ft/sec, the gust field traverses the aircraft at 50 ft/sec. While the latter process is not a very appealing artifice mathematically, it is necessary in order to avoid unrealistic time lags in the gust definition equations and flying the aircraft in a constant up or down-draught at hover.

A penetration distance G (ft.) is defined which represents the distance that the aircraft reference hub centroid has penetrated into the gust. Initially the gust front is assumed to be close to the edge of the rotor disk in the upwind direction. A rearward approaching gust is not possible without further manipulation of the model. The propagation rate of the gust field across the rotor is defined by V_{FLD} which then allows the penetration of any blade-segment, to be calculated (GPR_{jk} , see figure 5.9.1.3).

5.9.1 Description (Continued)

For the discrete gusts GPR_{jk} is introduced explicitly into the profile equations and the gust increment can be added directly. However, for the continuous gust case, a table of gust values, determined at fixed time (distance) intervals, (TABINK) are available. These data are obtained by passing independent, Gaussian, unit R.M.S.noise signals, produced by passing uniformly distributed white noise through the inverse Gaussian distribution function (Reference 5.9.6-2), through the Dryden filters. The assumption is made that perturbations in speed and heading are small enough such that the time constants in the gust functions can be considered constant, and that data can be loaded into the tables at fixed displacement intervals. These assumptions are consistent with the frequency/airspeed constraints of the Dryden Model application.

The gust velocities generated by either discrete or continuous functions, are in an axis set defined by the horizontal gust front. Three transformation matrices are required to orient into the blade axes and one for the body axes. These velocities are added to the other local velocities at the various stations.

The vertical gust component contributes to the total inflow of the main rotor. Because a basically uniform inflow is assumed in the Gen Hel rotor simulation, the change in inflow can be simulated by adding a representative velocity over the whole disc. The division of the blade into segments in Gen Hel is such as to give equal areas of swept annuli, making it possible to take a simple mean as the representative velocity of the additional inflow. Following the transformation of the z-direction component from space to (through body) shaft axes, the mean incremental velocity (VGAVMR) can be added to the downwash equation to compensate the total inflow.

The gust velocity at the fuselage is assumed to be the same value experienced at the rotor hub. The empennage velocities are based on the hub velocity with an approximate time delay to account for the penetration of the specific component.

This model of gust penetration may be criticized on the grounds that the point fuselage airload used is not consistent with the detailed penetration of the rotor blades. Fixed wing simulations commonly overcome the distribution problem by introducing correlated non-inertial rotational rates due to gust (Reference 5.9.6-1).

5.9.1 Description (Continued)

It is felt that the separation of the tail used here, accounts for a sufficiently large portion of the non-rotor component gust distribution effects and that further terms (for which there are little if any data) are unnecessary. In the same vein it is sufficiently accurate (and convenient in the implementation) to assume the aerodynamic center of the fuselage to be at the c.g.

Discrete lateral gusts may be handled by orientation of ψ_w . However, the continuous gust case is invalidated by using any value other than zero for ψ_w , due to apparent frequency shifts in the gust spectrum.

5.9.5 Data

The only data of concern here are the continuous gust power spectrum parameters. All other data is defined elsewhere in Gen Hel or is arbitrary (e.g. V_{HGAMP} and G_{HDIS} describing a discrete gust).

The following values are taken from Reference 5.9.6-1:

	Altitude (h) ≤ 1750 ft	Altitude (h) > 1750 ft
L_u	1750	$145 h^{1/3}$
L_w	1750	h
σ_u	$\sqrt{L_u/L_w} \sigma_w$	

(For lateral gusts, $\sigma_v = \sigma_u$ and $L_v = L_u$.)

5.10 Helicopter Motion Module5.10.1 Module Description

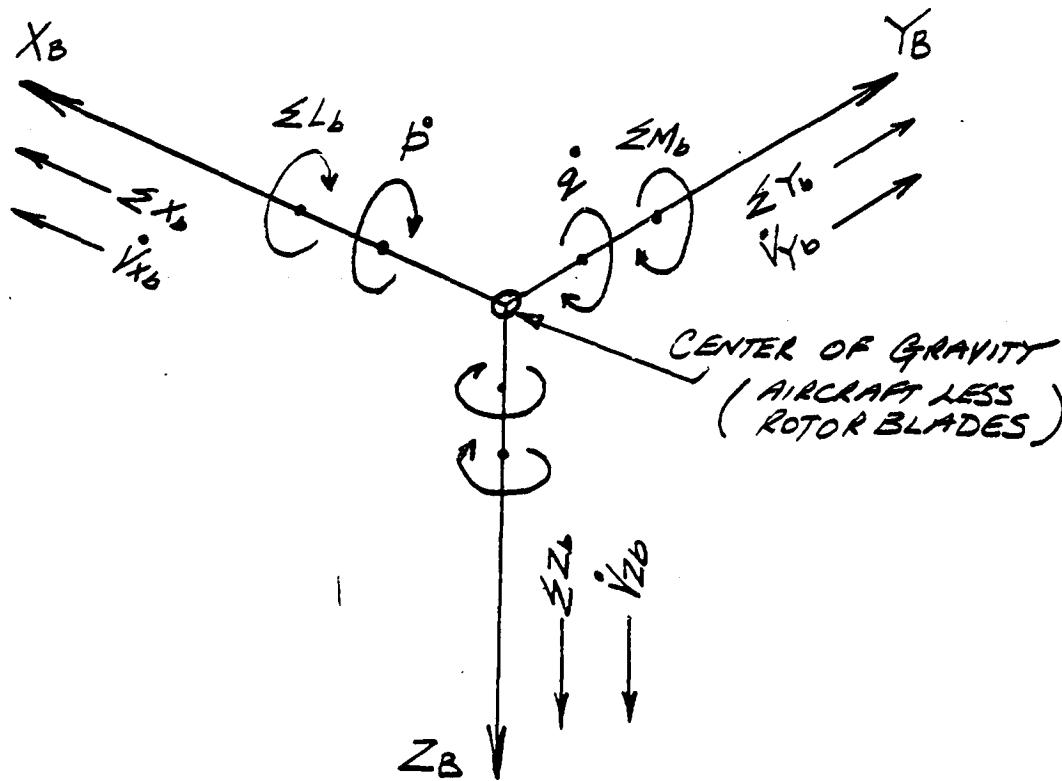

The forces and moments derived from the various simulated components of the aircraft are summed to develop the total external forces and moments at the airframe center of gravity in body axes, Figure 10.1.1. Introduced at this point, for convenience, are the gyroscopic moments resulting from rotating components. These equations are set up to cover any number of items of rotating mass aligned with the three body axes. The total external forces and moments are introduced into the general equations of motion from which the 6 components of acceleration are solved. It will be seen by comparing

with those on page 116 of Reference 10.6.1, that certain small terms have been eliminated. It should be noted that these are the equations of the aircraft less rotor blades, (which have their own degrees of freedom) and the appropriate mass is used. In order to obtain stable solutions under all operational conditions it is recommended that some velocity prediction technique be used in the determination of the body axes velocities, as presented. It should also be noted that since the p and r equation are coupled, they should be solved simultaneously as written. The Euler angular rate equations are given, followed by the body to space velocity axes transformation. Large angles are assumed.

The three component equations of motion for any specified point on the helicopter are presented in general form basically for output. However, lateral acceleration is fed back to the control system. It is recommend that at least two entries to these equations be provided to cover subsequent analyst requirements. The remaining equations in this section are provided for analyst output.

6.0 DEFINITION OF THE BLACK HAWK COCKPIT

6.1 Overall Cockpit Arrangement

The overall layout of the cockpit environment is shown on the photograph, Figure 1.1. This general view is supported by identification of cockpit components on Figures 1.2a and 1.2b. The cockpit geometric definition, relating to the pilot's seat, controls and instrumentation, is presented on Figures 1.3a, 1.3b and 1.3c as 3-view general arrangement drawings. Diagrams defining the upper and lower consoles are shown on Figures 1.4 and 1.5 respectively. The most significant items are the switching functions on the upper console and the Stabilator/Auto Flight Control Panel on the lower console. The flight instrument panel arrangement is shown on Figure 1.6.

6.2 Pilot's Primary Controls

A diagram of the pilot's cyclic stick grip is presented on Figure 2.1. The grip incorporates the following functions of significance:

Stick trim - provides for lateral and longitudinal stick trim at $1/2''/\text{sec}$.

Trim release - while depressed the force system is deactivated leaving a limp stick.

A diagram of the pilot's collective stick grip is presented on Figure 2.2. A friction device on the pilot's lever can be turned to adjust the amount of friction and prevent the collective stick from creeping.

6.3 Control Range Characteristics

The control motion, both in terms of control displacement in inches of travel and angular sweep are presented on Figure 3.1. Also provided are the corresponding angular outputs at the rotor head.

6.4 Control Force Feel Characteristics

The control forces, gradients and breakouts for the primary controls are given on Figure 4.1. The values presented were derived from measurements at the 50% control position.

More detailed information concerning all aspects of the cockpit may be obtained from References 6.5.1 through 6.5.4.
